(Received 14 February 2012; accepted 30 April 2012; published online 17 May 2012)

We describe a hybrid vacuum system in which a single ion or a well-defined small number of trapped ions (in our case Rb) can be immersed into a cloud of ultracold neutral atoms. This apparatus allows for the study of collisions and interactions between atoms and ions in the ultracold regime. Our setup is a combination of a Bose-Einstein condensation apparatus and a linear Paul trap. The main design feature of the apparatus is to first separate the production locations for the ion and the ultracold atoms and then to bring the two species together. This scheme has advantages in terms of stability and available access to the region where the atom-ion collision experiments are carried out. The ion and the atoms are brought together using a moving one-dimensional optical lattice transport which vertically lifts the atomic sample over a distance of 30 cm from its production chamber into the center of the Paul trap in another chamber. We present techniques to detect and control the relative position between the ion and the cloud.

I. INTRODUCTION

In recent years, both the fields of cold trapped ions and of neutral, ultracold atomic gases have experienced an astonishing development. Full control has been gained over the respective systems down to the quantum level. Single ions can be selectively addressed and their quantum states can be coherently manipulated and read out. The collective behavior of neutral atomic quantum gases can be mastered by controlling the particle-particle interactions, temperature, and physical environment.

Over the last two decades increasing efforts have been made to study cold collisions between ions and neutral particles. One approach is to study collisions in a cold He buffer gas (see, for example, Refs. 3–6). Another approach for collisions in the regime of a few K uses neutral, velocity-selected particles from a beam of molecules to collide with trapped ions.7 In recent years, collisions between atoms in a magneto-optical trap (MOT) and trapped ions have been observed.8–13 In 2010, in parallel to the group of M. Köhl14–16 our group has finally demonstrated immersing trapped ions in a Bose-Einstein condensation (BEC) of Rb atoms at nK temperatures.17

Here, we describe the hybrid apparatus used for our atom-ion collision experiments in detail. A central design concept of our setup is the spatial separation of the BEC apparatus - where the ultracold atoms (or a BEC) are produced - from the ion-trapping region, where the atom-ion collision experiments are performed. This way we gain valuable optical access to the atom-ion interaction region, that is necessary for trapping, manipulating, and detecting the atoms and ions. Furthermore, the separation and isolation of the production sites ensure that any mutual disturbance between the radiofrequency (rf) Paul trap and the rf used for forced evaporative cooling of the atomic sample is minimized. To transport the atoms over 30 cm from their place of production to the trapped ions, we employ a moving one-dimensional (1D) optical lattice.

As demonstrated in a first set of experiments,17 the apparatus enables us to study elastic and inelastic atom-ion collisions in the ultracold regime.18,19 We plan to investigate cold chemical reactions and the controlled formation of cold molecular ions, topics which recently gained considerable interest (see, for example, Refs. 20 and 21). Furthermore, the apparatus allows for carrying out other interesting lines of research. There are proposals to study the dynamics of charged impurities in a quantum degenerate gas,22–24 charge transport in a gas in the ultracold domain,25 or the formation of a mesoscopic molecular ion.26

The article is organized as follows: Sec. II describes the layout of the multi-chamber vacuum apparatus. In Sec. III, the design and the operation of the ion trap are discussed. Section IV addresses the preparation of the ultracold atom cloud in the BEC apparatus and its optical transport into the science chamber, in which the ion trap is located. In particular, we describe an experimental procedure based on atom-ion collisions used to precisely position the atom cloud with respect to the ion.

II. THE VACUUM APPARATUS

The vacuum apparatus consists of three main building blocks. A MOT chamber for trapping and laser cooling Rb...
FIG. 1. Layout of the vacuum apparatus in a partially exploded view: The science chamber (upper section) is connected to the BEC chamber (in the lower section) via a differential pumping stage (turquoise) along the dashed vertical axis. The MOT chamber (green) and the BEC chamber (red) which form the lower section are also connected via a differential pumping stage (turquoise). The science chamber exhibits a large DN200CF flange (blue) on top, the “science flange,” onto which the ion trap (not shown here) is mounted. A channeltron detector (brown) is connected along the axis of the linear ion trap. All three chambers are evacuated by their own pumping sections (grey). (Note: For better visibility the upper section is rotated clockwise by 90° around the dashed vertical axis.)

FIG. 2. Top view of the vacuum system: The science chamber (red), covers up the BEC chamber (not visible).

Atoms. A BEC chamber for evaporative cooling of the Rb atoms. A “science chamber” that houses the ion trap and where the ion-atom collision experiments take place. The apparatus has two floors: MOT chamber and BEC chamber form the lower section. The science chamber, forming the upper section, is located 30 cm above the BEC chamber (see Figures 1 and 2). The three vacuum chambers are connected via two differential pumping stages, each consisting of a differential pumping tube as well as a gate valve. If necessary, the vacuum chambers can be separated from each other by closing the gate valves. A series of vacuum gauges, pumps, and valves is used to evacuate the system and to determine the pressure. By baking out the setup at temperatures between 180 °C and 250 °C, ultrahigh vacuum (UHV) conditions are established in all three chambers. When in operation, the pressures are approximately $10^{-9}$ mbar in the MOT chamber and $10^{-11}$ mbar in the BEC chamber and the science chamber.

A. Lower section: BEC apparatus

The stainless steel (AISI 316L) MOT chamber features 10 optical viewports, which are required to implement the MOT laser beams, to connect to the Rb vapor source, to pump the chamber and to move the atoms out of the MOT chamber towards the BEC chamber. An ion getter pump\(^{27}\) is used to keep the MOT chamber at UHV conditions, as measured by an UHV pressure gauge (Bayard Alpert type).\(^{28}\)

The Rb vapor source is an ampule filled with bulk Rb and He as an inert gas.\(^{29}\) Since Rb is very reactive when exposed to air, the ampule is not cracked until the surrounding “oven section” has been evacuated. Once Rb has been released from the ampule, the pressure in the oven section is determined by the Rb vapor pressure, which is $4 \times 10^{-7}$ mbar at room temperature. As a consequence, the pressure in the center of the MOT chamber increases from its original value of $10^{-11}$ mbar to a few times $10^{-9}$ mbar and is then completely dominated by the...
Rb vapor. If necessary, the vapor pressure can be adjusted by heating the Rb source or by changing the setting of the valve which separates the oven section from the MOT chamber.

The pressure in the BEC chamber is kept below $10^{-11}$ mbar using a combination of a titanium sublimation (TiSub) pump and an ion getter pump. At this pressure, we achieve lifetimes of the atom cloud of more than 2 min which is sufficient to carry out rf evaporative cooling.

In order to maintain a pressure gradient of $p_{\text{MOT}} / p_{\text{BEC}} \approx 10^2$, a differential pumping tube is used to separate the MOT and the BEC chamber. Since the size of the atom cloud, which has to be transported through the tube, amounts to a few millimeters, we chose the tube diameter to be 8 mm. Molecular flow calculations then determine the tube length to be 115 mm.

The design of the BEC chamber is shown in Figs. 3 and 4. After laser cooled atoms from the MOT are magnetically transported into the BEC chamber, evaporation in a quadrupole-Ioffe configuration (QUIC) trap brings the atoms to BEC or close to BEC. Afterwards they are vertically transferred to the ion trap in the science chamber. The QUIC traps are typically used in combination with a glass cell, as the Ioffe coils need to be placed quite close to the atoms. In our setup where the BEC chamber is physically connected along the horizontal (to the MOT chamber) and the vertical (to the science chamber) direction, strong shear forces are acting on the chamber walls. For this reason, we chose stainless steel instead of glass for the construction of the BEC chamber. To minimize the distance between the atoms and the Ioffe coil, the BEC chamber exhibits a special insertion slot with a thin end wall into which the Ioffe coil can be placed (see Fig. 4).

The BEC chamber features four optical axes. The first axis points along the vertical direction and is needed for the optical transport of atoms from the BEC chamber into the science chamber (transport axis). On both ends small DN16CF flanges are used, so that the QUIC quadrupole coils can be easily mounted. The second axis (imaging axis) is used for imaging the ultracold atoms. DN40CF viewports are used on both ends, in order to allow for a good imaging quality. In addition, optical access along the magnetic transport axis is desirable, in order to be able to image the atom cloud at any intermediate position of the transport. Finally, the BEC chamber features a fourth optical axis (optical dipole trap axis), which is currently not used in our experiments but could, for example, be employed for the addition of a dipole trapping beam. In order to utilize the full pumping speed of our ion pump, the pumping section is connected to the BEC chamber via a DN100CF flange.
directions we use four blade electrodes, which are mounted symmetrically at a distance of \( r_0 = 2.1 \text{ mm} \) from the trap axis. A rf of \( \Omega = 2\pi \times 5.24 \text{ MHz} \) with an amplitude of \( 2 \times U_{rf} = 1400 \text{ V}_{pp} \) is applied to two of the four blades, whereas the other two are grounded. The rf is generated by a commercially available function generator \(^{34}\) and subsequently amplified by a 5 W rf amplifier from Minicircuits.\(^{35}\) The power at the output of the amplifier is inductively coupled to the trap electrodes via a ferrite-toroid transformer (see Fig. 6). The impedance of the trap is matched, so that the supply voltage is resonantly enhanced by a factor of 30. Trapping along the axial direction is achieved by applying dc voltages on the order of 100 V to the two endcap electrodes which are located on the trap axis at a distance of 7 mm from the trap center. Typical ion trapping frequencies for the parameters given above are \( \omega_{rad} \approx 2\pi \times 250 \text{ kHz} \) and \( \omega_{ax} \approx 2\pi \times 80 \text{ kHz} \) for Ba\(^+\) and \( \omega_{rad} \approx 2\pi \times 390 \text{ kHz} \) and \( \omega_{ax} \approx 2\pi \times 100 \text{ kHz} \) for Rb\(^+\). As expected, the trap frequencies of our ions in the linear Paul trap scale in first order as \( \omega_{rad} \propto 1/m \) and \( \omega_{ax} \propto \sqrt{1/m} \). The stability factor \( q \) is generally given by \( q = 2eU_{eff}/(m\gamma^{-2}\Omega^2) \),\(^{36}\) where \( \gamma = 1.53 \) is a numerical factor that depends on the exact geometry of the rf electrodes. Our Paul trap allows stable trapping of both Ba\(^+\) and Rb\(^+\), since \( q \ll 1 \) for both species \( (q = 0.13 \text{ for Ba}^+ \text{ and } q = 0.21 \text{ for Rb}^+) \).

All electrodes are made of non-magnetic, high-grade, stainless steel of type AISI 316L. This material is specified to have a magnetic permeability of \( \mu < 1.005 \). The blades are produced by electrical discharge machining, which allows for a higher precision and a smaller surface roughness as compared to milling. The electrodes are mounted onto two insulating parts, which are made out of a machinable glass ceramic (MACOR). This material has a very low outgassing rate and is thus well suited for UHV applications.

### B. Loading and laser cooling of ions

We load the Paul trap (Fig. 7) with either \(^{138}\text{Ba}^+\) or \(^{87}\text{Rb}^+\) ions. To work with Ba\(^+\), we run a current of about 8 A (corresponding to 6 W) through the commercially available Ba source\(^{37}\) (see Fig. 5). It is a stainless steel tube with a diameter of 2 mm, which is filled with metal alloy containing Ba. Ba vapor is created through sublimation out of the alloy. In the center of the trap, the neutral Ba atoms emitted by the oven are photoionized using a diode laser operating at 413 nm.\(^{38}\) A few mW of laser power are used to drive the resonant two-photon transition from the ground state to the continuum via the \( ^3D_1 \) state. With this procedure we are able to load single ions into our trap within a few minutes.

We perform Doppler cooling of the \(^{138}\text{Ba}^+\) ions on the \( ^6S_{1/2} \rightarrow ^6P_{1/2} \) cycling transition, which has a transition wavelength of 493 nm and a linewidth of 15.1 MHz. The corresponding Doppler temperature is 360 \( \mu \text{K} \). The 493 nm cooling light is generated via frequency doubling of a 986 nm diode laser. Both the diode laser and the frequency-doubling stage are part of the commercially available system “DL SHG” from Toptica. To stabilize the frequency of the 493 nm light, the 986 nm laser is locked to a temperature-stabilized optical cavity using the well-established Pound-Drever-Hall

![FIG. 6. Ferrite-toroid transformer with a turns ratio of 2:36. By adjusting the capacity \( C_r \), the impedance of the trap (corresponding to \( C_T \)) is matched and the ratio between the output and the input voltage \( (V_o/V_i) \) is maximized. In order to be able to monitor the output voltage, a capacitive voltage divider \( (C_D1 \text{ and } C_D2) \) is used.](image)

![FIG. 7. Linear ion trap (Paul trap). The trap consists of four rf electrodes (blue) for confinement in the x-y plane, two endcap electrodes (golden) for confinement along the z axis, and four compensation electrodes (green) for the generation of dc electrical fields in the x-y plane. All electrodes are made of stainless steel AISI 316L. The dimensions are given in mm.](image)
method. An additional “repumper” laser at a wavelength of 650 nm is needed, in order to bring the atoms from the metastable $5\text{D}_{3/2}$ state back into the cooling cycle. The repumper is a home-made external-cavity diode laser, which features an anti-reflection-coated laser diode to guarantee stable lasing at the desired wavelength. The frequency of the repumper is stabilized using the same locking scheme as for the 986 nm laser.

To work with clouds of Rb$^+$ ions, we transport ultracold Rb atoms into the center of the Paul trap and ionize them using the imaging laser at 780 nm together with the ionization laser at 413 nm. The resonant imaging laser brings the Rb atom into the $5\text{P}_{3/2}$ state, so that the 413 nm laser can then drive the transition into the continuum. Since we start with an ultracold trapped atom source, this ionization procedure is very fast and efficient. It allows for loading clouds of Rb$^+$ ions into the Paul trap within a few milliseconds.

We employ a different scheme when performing experiments with single Rb$^+$ ions. In this case, we first load a single Ba$^+$ ion into the Paul trap following the procedure described above. Then we let the Ba$^+$ ion interact with ultracold Rb atoms until the charge transfer process $\text{Rb} + \text{Ba}^+ \rightarrow \text{Rb}^+ + \text{Ba}$ has taken place. This takes typically a few seconds. The newly formed Rb$^+$ ion is “dark,” as it cannot be detected via standard fluorescence imaging due to the lack of an accessible cycling transition. Therefore, Rb$^+$ has to be detected via its elastic collisions with the neutral atoms and the corresponding atom losses. The newly formed Rb$^+$ ion is available for thousands of experimental cycles, since its lifetime in the Paul trap is typically on the order of days.

C. Micromotion

In addition to the pseudopotential generated by the rf drive, dc stray electric fields are also present. Possible sources of these fields are imperfections in the fabrication of the trap or patch charges on the ceramic parts. Such surface charges could be generated by our blue Ba$^+$ lasers (413 nm and 493 nm) via the photoelectric effect. In any case, the dc fields push the ion out of its ideal trap location, the rf node, into a region of non-vanishing rf, leading to the so-called “excess micromotion” of the ion. In order to minimize this enhanced micromotion, we have to compensate the dc electric offset fields at the position of the ion. To compensate electrical offset fields in the axial direction, we can apply corresponding voltages to the endcaps of the Paul trap. To generate compensation fields along the radial direction, four “compensation electrodes” (two for each direction) are added to the design of the linear Paul trap. By placing the electrodes at a distance of 9.35 mm from the trap axis and applying a voltage $U_{\text{comp}}$, we are able to generate dc compensation fields of $E_{\text{comp}} = \beta U_{\text{comp}}$, where $\beta = 3.1 \text{ m}^{-1}$. A simple and in our system very accurate method to detect excess micromotion is to determine the position shift of the ion when the rf amplitude is changed. By adjusting the compensation fields such that the position shift is minimized, we can assure that the potential minimum nearly coincides with the rf node. This method works nicely for electric fields along the vertical direction. However, for the compensation of fields along the x axis a different method has to be used, since we are not able to measure the x position of the ion with high accuracy. One possibility, realized in our setup, is to modulate the amplitude of the rf drive. Setting the modulation frequency equal to the trap frequency leads to resonant heating of the ion, which can be detected via a smearing of the ion fluorescence. The heating is particularly strong when the ion is not in the rf node. Hence, we can adjust the compensation fields by minimizing the heating. In early experiments, using the methods described here, we were able to reduce the dc electric fields at the position of the ion to about 1 V/m.

D. Imaging methods

We detect the ion by collecting its fluorescence using a high-aperture laser objective (HALO) from Linos (see Fig. 7). The HALO has a numerical aperture of NA = 0.2 and a focal length of $f = 60$ mm, which enables us to detect about NA$^2/4 \approx 1\%$ of the spontaneously emitted photons. It is placed inside the vacuum chamber at a distance of $f = 60$ mm from the trap center. Since the original mount of the HALO is anodized and generally not designed to be put into a UHV environment, it was exchanged by a UHV-capable aluminum mount. This new mount features an air vent in order to avoid slow outgassing of air that is enclosed in between the different lenses of the objective.

The collimated fluorescence light exits the chamber through a DN63CF AR-coated viewport. An $f = 300$ mm achromat is then used to focus the light onto the EM-CCD chip of an Andor Luca(S) camera. Diffraction at the aperture of the HALO ultimately limits the resolution of the imaging system to about 1.5 $\mu$m, which is an order of magnitude smaller than the typical distance between two neighboring ions of an ion string.

Absorption imaging of the cloud of neutral atoms is also done with the HALO. To separate the Rb imaging beam (780 nm) from the Ba$^+$ fluorescence light (493 nm), we use a dichroic mirror. Together with the HALO, an $f = 200$ mm achromat forms the objective for the neutral atom detection. The large spacing between the ion-trap electrodes allows for taking the images not only in situ but also after a free expansion of the atom cloud of up to 15 ms.

IV. PREPARATION AND DELIVERY OF ULTRACOLD ATOMIC SAMPLES

After the ion has been trapped, we start the production of an ultracold atom cloud in the lower section of the vacuum apparatus. The time needed to create a Rb cloud with $2 \times 10^6$ atoms at a temperature of about 1 $\mu$K is approximately 35 s. Another 5 s are required to transport the atom cloud into the science chamber and to perform further forced evaporative cooling in an optical dipole trap down to BEC or to cold thermal ensembles with typical temperatures of 100 nK.

A. MOT loading and magnetic trap

To operate the MOT, we have set up two external-cavity diode lasers tuned to the $5\text{S}_{1/2} \rightarrow 5\text{P}_{3/2}$ transition in $^{87}\text{Rb}$.

One of the diode lasers is locked to the $|F = 2\rangle \rightarrow |F' = 3\rangle$ cycling transition using the modulation transfer spectroscopy technique.\textsuperscript{41} The light from this laser is amplified with a tapered amplifier\textsuperscript{42} and sent through a polarization-maintaining optical fiber. After the fiber the total power of 250 mW is split up into six beams, all of them having a diameter of 30 mm. Using acousto-optical modulators (AOM) the cooling light is detuned to about $-3.5\Gamma$ relative to the cycling transition, where $\Gamma = 6$ MHz is the transition linewidth. Our second Rb laser is locked to the $|F = 1\rangle \rightarrow |F' = 1\rangle |F' = 2\rangle$ cross over line using the frequency modulation technique.\textsuperscript{43} This repumper laser is used to pump the atoms from the $|F = 1\rangle$ ground state back into the cycling transition. To operate the MOT, a total repump power of $6 \times 1.5$ mW is employed. The required magnetic field gradient of $B'_z = 8$ G/cm is generated by running a current of 5 A through a pair of anti-Helmholtz coils. This setup enables us to load about $3 \times 10^9$ Rb atoms from the background vapor into the MOT.

By turning off the magnetic field and detuning the MOT cooling beams to about $-8.5\Gamma$, we perform polarization-gradient cooling for a duration of 10 ms. In this way, the temperature of the atoms is reduced to about 40 $\mu$K. In a next step, the atoms are optically pumped into the lowest magnetically trappable state $|F = 1, m_F = -1\rangle$ and subsequently loaded into a magnetic quadrupole trap. The trap is generated by running 80 A through the MOT coils leading to a magnetic field gradient of $B'_z = 130$ G/cm, which is sufficient to hold the atoms against gravity. The number of the atoms now amounts to nearly $1 \times 10^9$.

B. Magnetic transport and QUIC trap

Following the concept described in Ref. 44 (see also Ref. 45), the cold atom cloud is transported magnetically from the MOT chamber to the BEC chamber. The magnetic transport line is shown in Figure 8. For the transport, we employ 13 pairs of anti-Helmholtz coils and an additional “push coil”. By properly ramping the currents through the coils, it is possible to smoothly shift the position of the atoms, which are trapped in the magnetic field minimum. We are able to move the cloud over a distance of 431 mm within 1.5 s. The final particle number after transport is typically $5 \times 10^8$, corresponding to an overall transport efficiency of about 50%.

![FIG. 8. Magnetic transport line: The neutral atom cloud is transported over a distance of 431.2 mm from the MOT chamber (green) to the BEC chamber (golden). Together with their respective aluminum housings (blue), the required magnetic field coils (brown) are mounted to the stainless steel chambers.](image)

FIG. 8. Magnetic transport line: The neutral atom cloud is transported over a distance of 431.2 mm from the MOT chamber (green) to the BEC chamber (golden). Together with their respective aluminum housings (blue), the required magnetic field coils (brown) are mounted to the stainless steel chambers.

The temperature of the atom cloud increases from initially 150 $\mu$K to about 230 $\mu$K.

At the end of the transport the atoms are loaded into the QUIC trap, which consists of the so-called quadrupole coils together with a small diameter end coil (Ioffe coil) (see Figs. 3 and 9). In a first step, the current through the quadrupole coils is ramped from 16 A (used for the transport) to 36 A and thus the magnetic field gradient is increased from $B'_z = 130$ G/cm to $B'_z = 320$ G/cm. Subsequently, we ramp the current through the Ioffe coil from 0 to 36 A. At the end of the ramp, a single power supply is used to drive the quadrupole coils and the Ioffe coil, which are connected in series. Having all the QUIC coils wired up in the same circuit minimizes heating of the atom sample and leads to a 1/e lifetime of thermal atom clouds of about 2 min. The coil system generates an offset magnetic field of about 2 G and a nearly harmonic potential with trapping frequencies of $(\omega_x, \omega_y, \omega_z) = 2\pi \times (105, 105, 20)$ Hz, where the $z$-direction is along the Ioffe axis.

We perform rf-induced forced evaporative cooling to reduce the temperature of the atom cloud by more than two orders of magnitude. To selectively remove hot atoms, a small coil with 3 turns and a diameter of about 20 mm is placed inside the vacuum at the bottom of the BEC chamber at a distance of 13 mm from the atoms. The coil is driven with 30 dBm of rf power and the frequency is ramped from initially 60 MHz down to about 3 MHz within 20 s. With this procedure we are in principle able to produce Bose-Einstein condensates of up to $3 \times 10^5$ atoms. However, for our experiments we stop the evaporation before we reach BEC, resulting in a thermal atom cloud with about 1 $\mu$K temperature and an atom number of about $2 \times 10^6$. As compared to the BEC, the thermal cloud experiences much smaller losses due to three-body collisions during the subsequent optical transport into the science chamber.

![FIG. 9. A moving optical standing wave is used to transport the ultracold atoms vertically from the QUIC trap in the BEC chamber into ion trap in the science chamber. The distance between QUIC trap and Paul trap is not to scale.](image)
C. Optical transport of ultracold atoms

One of the key features of the experimental setup is the vertical long-distance optical transport of the ultracold atoms from the BEC chamber into the science chamber. An illustration is given in Fig. 9. We follow a scheme similar to that described in Ref. 46 (where, however, the optical transport was in horizontal direction). The ultracold atoms are first adiabatically loaded from the QUIC trap into a vertical far red-detuned 1D optical lattice within 300 ms. As the lattice is set into motion it drags along the atoms, like an elevator. After a transport distance of about 30 cm, corresponding to the distance between BEC chamber and science chamber, the lattice is brought to a halt and the atoms are transferred into a crossed dipole trap.

In order to load the atomic cloud into the 1D optical lattice, it first has to be shifted from its location close to the Ioffe coil (where the evaporation takes place) back to the center of the quadrupole coils which is about 5 mm away. This shift is controlled via magnetic fields from various magnetic coils. Motion along the Ioffe axis (see Fig. 3) can be induced by changing the current through the quadrupole coils while keeping the Ioffe current constant. For position changes along the imaging direction (which is orthogonal to the Ioffe axis), we operate the last pair of the magnetic transport coils. The exact position along the (third) vertical axis is irrelevant, since the atoms can be loaded into any antinode of the optical lattice. Nevertheless, we added a levitation coil (see Fig. 9) to the system, which can be used to control the vertical position of the atoms. This way we can prevent the atoms from leaving the region to which we have good optical access. In order to optimize the overlap between the magnetic trap and the optical standing wave, we perform Bragg diffraction of the magnetically confined atom cloud using the 1D optical lattice. We adjust the position of the QUIC trap such that the Bragg diffraction and thus the overlap is maximal. We can determine the lattice depth experienced by the atoms by measuring how the diffraction pattern changes as we vary the length of the Bragg diffraction pulses. For the experimental parameters used in our setup about 100 lattice cells are occupied by the atoms.

The optical lattice is formed by two counterpropagating collimated Gaussian laser beams at $\lambda = 1064$ nm with a power of 1.25 W and 0.5 W, respectively. For both lattice beams, the diameter at the waist was chosen to be about 500 $\mu$m, so that the divergence of the beams can be neglected. The light is derived from a home-made fiber amplifier which is seeded by a diode-pumped solid-state laser. Due to its very low spectral linewidth ($\approx 1$ kHz), the laser is well suited for the generation of an optical lattice. Both beams are sent through AOM in order to control their frequency as well as their intensity. At the beginning of the transport, both AOMs are driven with a rf of 80 MHz. For the transport scheme to work, it is essential that both rfs are phase locked to each other throughout the entire transport sequence because sudden phase jumps would in general lead to atomic loss. Therefore, the rf signals are generated using digital synthesizers (AD9854) which can be locked to the same external reference oscillator. In order to make the standing wave pattern move with a velocity $v = \Delta v \lambda /2$, we detune the frequency of the upper lattice beam by $\Delta v$. When the drive frequency of an AOM is modified, the diffraction angle and the beam path of the laser beam changes. To preserve the alignment of the lattice throughout the transport, we couple the upper lattice beam through an optical fiber before sending it to the experiment. The fiber coupling limits the power of the upper lattice beam to about 0.5 W. The lattice beams enter and exit the vacuum system through AR-coated viewports, which are attached to the chamber at an angle of about $4^\circ$ with respect to the (vertical) transport axis. By this means, we ensure that the reflections off the viewports do not interfere with the standing wave.

Due to the large waist of the laser beams, the confinement of the atoms in the optical lattice sites is more than two orders of magnitude stronger in the axial (transport) direction than in the radial direction. The strong axial confinement prevents gravity from pulling the atoms out of the lattice potential even for moderate laser intensities. Even in the presence of weak heating during transport, the temperature of the atom cloud stays below 1 $\mu$K. This is due to evaporative cooling from the lattice potentials which are only several $k_B \times \mu K$ deep.

The ramp for the relative frequency shift, $\Delta v(t)$, between the two lattice beams is derived from the ramp for the vertical atom position $y(t)$. Both quantities as well as the velocity $v(t)$ are plotted in Fig. 10 as a function of time. During transport, the AOM frequencies and thus also the value for the detuning $\Delta v(t)$ are updated every 40 $\mu$s. For a given transport distance $D$, the transport time $T$ and the form parameter $n$ (see Fig. 10) are optimized for maximum transport efficiency. In our case, we have $D = 304$ mm and find a maximum efficiency of 60% for $T = 0.9$ s and $n = 4.5$, ending up with $1.5 \times 10^6$ Rb atoms in the science chamber.

The optical transport may be extended to even larger distances than described above. As a proof of principle, we have transported the atom cloud from the BEC chamber over 45 cm to the very top of the science chamber and then back into the BEC chamber again. In this experiment, the total round trip distance of 90 cm was only limited by the length of our vacuum apparatus.

![FIG. 10. Optical transport of ultracold atoms. (a) A ramp of the form $y(t) = B[tanh (n(2t - T/2) + tanh(n)/2tanh(n))$ is chosen for the vertical position of the atoms versus time, where $B = 304$ mm is the transport distance, $T = 0.9$ s the transport time, and $n = 4.5$ the form parameter. (b) From the ramp $y(t)$, we can derive the velocity $v(t)$ of the atoms and the corresponding relative detuning (frequency shift) $\Delta v(t)$ between the two lattice beams.](image-url)
D. Adjusting the lattice transport distance

The atom transport has to be adjusted such that it stops at the exact location of the trapped ion. A simple method for this would be to use the same camera to image the locations of the ion and the lattice held atomic cloud and to adjust the transport such that they coincide. However, in our setup this is not possible since we image ions and atoms with two different cameras. We thus use a different approach which proceeds in two steps. First, an approximate value for the transport distance \( D \) is found by determining the position of the atom cloud relative to the rf electrodes via standard absorption imaging. We choose \( D \) such that the atoms end up roughly in the center of the ion trap midway in between the lower and the upper electrodes.

Second, for a more precise adjustment, we load a cloud of hundreds of ions into the Paul trap. Afterwards, we transport a freshly prepared atom cloud to the ion cloud such that the two species get into physical contact. The ion cloud locally depletes the atom cloud which is measured by taking absorption images of the atom cloud after 1 s of interaction time (see Fig. 11). The depletion is due to elastic collisions between atoms and ions which simply get kicked out (see Fig. 11). The depletion region is located in the center of the atomic cloud, indicating a good vertical alignment. The pictures are taken after a time-of-flight of 12 ms.

![Image 54x602 to 294x739](image)

FIG. 11. Absorption images of the atom cloud after the interaction with a localized ion cloud. The atoms are transported to the ion trap and brought into contact with the ion cloud for 1 s. The Paul trap is loaded with a cloud of hundreds of Rb\(^{+}\) ions, which are responsible for the localized loss of atoms around the ion trap center. Outside of the ion trap center the atom loss is very small, as the atoms, being trapped in lattice sites, cannot get into contact with the ion cloud. The transport distance is varied between 303.90 mm and 303.925 mm. Arrows indicate where the ion cloud has depleted the neutral atomic ensemble. For a transport distance of 303.91 mm, the depletion region is located in the center of the atomic cloud, indicating a good vertical alignment. The pictures are taken after a time-of-flight of 12 ms.

E. Loading of the crossed dipole trap and evaporative cooling

After transport, the atoms are loaded into a crossed optical dipole trap, formed by the lower lattice beam and an additional horizontal dipole-trap beam. This additional trapping beam is derived from the same laser as the lattice beams and propagates horizontally along the \( x' \) axis (see Fig. 12), which is at an angle of 45° with respect to the \( x \) axis. It has a waist of 50 \( \mu \)m and is ramped up to a power of 1 W within 1 s. Subsequently, the power of the upper lattice beam is ramped down to zero within 1 s and a crossed optical dipole trap is formed. We are able to load about 50% of the atoms from the 1D optical lattice into this crossed dipole trap while keeping the temperature of the sample below 1 \( \mu \)K.

In the next step, the depth of the dipole trap is lowered within 4 s to evaporatively cool the atoms and to end up with a BEC of typically \( 10^5 \) atoms. If we prefer to work with a thermal atom cloud \( (T = 100 \text{ nK}) \), the evaporation is stopped immediately before the onset of Bose-Einstein condensation. The lifetime of a thermal atom cloud is typically on the order of \( 10^2 \) s.

F. Fine alignment of the crossed dipole trap

We control the position of the crossed dipole trap dynamically with the help of AOMs (see Fig. 12). For a typical AOM with a center frequency of 80 MHz, the corresponding Bragg angle is about 10 mrad. Since the frequency bandwidth is on the order of 10%, the diffraction angle can be varied by about 1 mrad. For distances between the AOMs and the science chamber on the order of 1 m, this results in a shift of the ion trap position by up to 1 mm.

The relative position of the dipole trap relative to the ion trap can be accurately measured by again looking at atomic collisional losses as previously described in Sec. IV D. However, this time we use a single ion (see Fig. 12). In order to precisely control the interaction time of the ion with the atomic cloud, the ion is at first positioned about 300 \( \mu \)m away from its proper location so that it cannot interact with the atoms. This is done by changing one of the endcap voltages of the ion trap midway in between the lower and the upper electrodes.

![Image 325x635 to 551x739](image)

FIG. 12. Probing the position of the optical dipole trap with a single ion. (a) First, the ion is moved away 300 \( \mu \)m from its normal position to prevent any collisions with the atoms during the final evaporation stage. This is done by changing one of the endcap voltages of the ion trap which moves the ion along the ion-trap axis (\( z \) axis). The position of the optical dipole trap is controlled by moving the laser beams with the help of AOMs. (b) By switching back to the original endcap voltages, the ion is moved back within several ms to its original position where it can now probe the local density of the atomic cloud.

linear ion trap. This moves the ion along the axis of the ion trap (z axis). Afterwards, the atom cloud is transported in from the BEC chamber and positioned by smoothly ramping the AOM frequencies. By quickly switching back the endcap voltages to their proper values, the ion moves back to its original position within 2 ms and starts colliding with the atoms, kicking them out of the trap. This procedure is illustrated in Fig. 12. We then measure the atom loss as a function of the dipole trap position (i.e., the AOM frequencies). A typical curve is shown in Fig. 13 for an interaction time of about 1 s, working with a thermal cloud of initially $5.5 \times 10^4$ atoms. Here, the same ion is used for all data points. (The micromotion of the ion was compensated to about 10 mK for these measurements.) The atom number reaches a minimum when the dipole trap is centered onto the ion. We can use this measurement to accurately overlap atom and ion trap along all three directions in space.

V. SUMMARY

In conclusion, we have designed a hybrid vacuum apparatus which allows for cold collision experiments between ultracold neutral atoms and trapped, cold, single ions. A main feature of this apparatus is the spatial separation of production of the ultracold atomic cloud and the location where experiments take place, i.e., the linear ion trap. In order to transport the atoms to the ion trap, we use a novel efficient optical elevator consisting of a moving optical lattice which bridges a vertical gap of 30 cm within 1.5 s. The use of a vertical transport also leads to a non-standard design of the BEC apparatus which houses a QUIC trap within a steel chamber. The overall layout of the apparatus is quite modular which has advantages in terms of stability and versatility, such that extensions can be added to the apparatus easily in the future. Also it helped to optimize the optical access to the region where ion-atom collision experiments take place. In addition to discussing the overall design, we also describe various alignment and optimization procedures, e.g., accurate positioning of the atomic cloud onto the ion trap. First experiments with the apparatus show promise for exciting research prospects in the future.

ACKNOWLEDGMENTS

We would like to thank Rudi Grimm for generous support during the built-up phase. We are grateful to Michael Drewsen and the group of Rainer Blatt for advice on the design of the ion trap. We thank Wolfgang Limmer for thorough proofreading of the article and help in editing. We thank Dennis Huss, Artjom Krukow, Andreas Brunner, and Wolfgang Schnitzler for several technical improvements of the setup. This work was supported by the Austrian Science Foundation (FWF) and the Deutsche Forschungsgemeinschaft (DFG) within the SFB/ TR21. S.S. acknowledges support from the Austrian Academy of Sciences within the DOC doctoral research fellowship program.
